18 Abstract

19 Specific treatments combining high temperatures of up to 150°C and moderate pressure of up
20 to 0.6 MPa have been applied to *Bacillus subtilis* 168 spores conditioned at different a_w levels
21 (between 0.10 and 0.70) corresponding to different residual water contents within the spore
22 core. The spores were treated as a dry powder in a pressurized nitrogen environment or in
23 water/glycerol solutions.

24 These thermodynamic conditions were intended to prevent any water evaporation from the
25 spore core during time/temperature treatments.

26 Our results clearly show that retaining liquid water in the core by applying pressure during the
27 treatment resulted in greater spore destruction (between 2.4 and 4.9 log at 150°C, 120 s and a_w
28 0.5 in powder) than the destruction observed after the treatment at atmospheric pressure (0.7
29 log), during which the water rapidly evaporated because its boiling point was reached.

30 Moreover, we found that the water activity level of the spore had a significant impact on spore
31 destruction: the higher the a_w level, the greater the spore inactivation.

32 We obtained similar results from spores heat-treated in powder and in water/glycerol solution
33 at the same a_w , confirming the strong influence of this parameter. We hypothesized that the
34 increased spore inactivation was related to the well-known thermal sensitivity of vital organic
35 molecules such as proteins, enzymes, and ribosomes in the presence of water.

36

37 Keywords

38 *Bacillus* spores – dry food – food powder - thermal sterilization – pressure – water activity

39

40 1. Introduction

41 Low water activity foods ($a_w < 0.6$), such as food powders, seeds, dried fruits, cakes, flakes,
42 spices and aromatic herbs, represent a large amount of food products consumed directly or
43 used as intermediate food products (Cuq et al., 2011). These products contain vegetative and
44 sporulated bacteria that cannot grow due to the low water activity level. Safety problems can
45 arise after rehydration before or during ingestion. To prevent such incidents, these products
46 must be decontaminated, but heat decontamination is more difficult for dry products than it is
47 for liquid products. Indeed, dried microorganisms are more heat-resistant (Grasso et al., 2014;
48 Laroche and Gervais, 2003) and heating without water could also rapidly cause burning
49 damage to the product. Among dried microorganisms, sporulated bacteria are particularly
50 resistant (Tiburski et al., 2014) and spores of *Bacillus* species can survive various drying and
51 heat treatments used in the food industry (Andersson et al., 1995). These spores have also
52 been seen to adhere to stainless steel and to resist cleaning in place (CIP) procedures in and
53 around food factories (Tauveron et al., 2006). These characteristics have obvious
54 implications, from equipment bacteria could contaminate food and therefore cause high
55 numbers of spores to be found in food products. Dried foods such as spices, milk powders and
56 cereal products are often quite heavily contaminated with spores, and when water becomes
57 available during food preparation these spores may germinate, leading to spoilage or food
58 poisoning (Logan, 2012). However, destroying bacterial spores is rather difficult, and most of
59 the techniques commonly used to treat dry foods result in very low spore inactivation (Silva et
60 al., 2013).

61 The most frequently used decontamination techniques for dry products are steam thermal
62 processing, irradiation and fumigation. However, steam adds undesirable moisture to dry
63 foods and causes color changes. Fumigation has been banned in most countries due to its
64 toxicity, and irradiation is strongly rejected by consumers. In addition, these decontamination

65 techniques cause loss of quality and sometimes low inactivation rates (Ghisleni et al., 2016).
66 Therefore, there is a need to develop new technologies to produce high quality and safe dry
67 food ingredients such as herbs and spices.

68 Though spices are non-perishable ingredients, once they are put in water-rich food products,
69 their natural or contaminant flora can quickly develop and multiply, consequently putting the
70 health of consumers at risk. This is an especially important issue for spices added to ready-to-
71 eat foods that are not subjected to further heat treatments (Van Doren et al., 2013).

72 Moreover the existence of pathogenic spores like *B. cereus* strains, that may cause foodborne
73 infections (Glasset et al., 2016) or like *Clostridium botulinum* strains that may sometimes
74 cause infant infection through dairy products (Doyle et al., 2015), is considered as a major
75 risk for the food industry.

76 It is thus important to decontaminate food powders efficiently, especially if these powders are
77 to be incorporated into a more complex preparation with a higher water content. The
78 decontamination of dried powders is difficult, and the difficulty correlates with the increasing
79 resistance of spores and vegetative forms to low water activity levels (Fine and Gervais,
80 2005b; Laroche et al., 2005; Laroche and Gervais, 2003; Tiburski et al., 2014).

81 Many authors have already shown that the low water activity or low water content in spores
82 could explain their high heat resistance and that water diffusion from or out of the spore core
83 is slowed (Knudsen et al., 2016; Loison et al., 2013; Nguyen Thi Minh et al., 2010b). In a
84 previous work, *Bacillus subtilis* spores have been reported to have a low water permeability
85 and suggested that the coat structure may be necessary for maintaining this low a_w (Knudsen
86 et al., 2016). In another manuscript, using a molecular rotor, the high viscosity of the internal
87 membrane of this spore was demonstrated and correlated this property with its barrier
88 properties (Loison et al., 2013).

89 In previous studies on spore thermal inactivation, *Bacillus subtilis* spores were shown to have
90 D-values which fell in the same range of pathogen spores like *B. cereus* and *B. anthracis*
91 (Montville et al., 2005). Nevertheless, large interstrain variations in spore heat resistance has
92 been regularly reported. For example, the presence of a specific operon (SPOVA2mob not
93 present in strain 168 used in this work) leads to increase the D value more than 100 times
94 (Krawczyk et al., 2017).

95 *B. subtilis* is also used as a surrogate for some pathogenic spores (Hu and Gurtler, 2017).
96 Moreover *B. subtilis* itself can induce food spoilage incidents particularly on bread
97 (Thompson et al., 1993).

98 Recently Tros et al. (2017) have shown that a large fraction of “slow” intracellular water
99 linked to proteins exists in the *Bacillus subtilis* spores and in a previous work (Tiburski et al.,
100 2014), the role of water in the heat resistance of dried *Bacillus subtilis* spores was also
101 investigated using Differential Scanning Calorimetry. The spore temperature was linearly
102 increased in pans with different pressure resistances. The results demonstrated that even in
103 dry external conditions, a water fraction stayed embedded in the spore core and that
104 maintenance of this core water content during heating dramatically increased spore
105 destruction. Infrared analysis of treated spores showed that the heat destruction was highly
106 related to protein denaturation and dipicolinic acid (DPA) release, which were maximized in
107 wet conditions.

108 This work was intended to apply these results to optimizing dried spore decontamination
109 based on preserving the initial water content of the spore core. The method used to prevent
110 water evaporation was to pressurize a hermetic container and consequently change the water
111 vapor equilibrium.

112 This study investigated the inactivation of dried *Bacillus subtilis* spores equilibrated at
113 different water activities by a treatment using high temperature and absolute pressure levels
114 from 0.1 to 0.6 MPa. *Bacillus subtilis* spores were already used as surrogates for pathogenic
115 spores (Hu and Gurtler, 2017). The applied pressure prevented the water in the samples from
116 boiling, thus allowing its initial water content to be maintained. The effect of
117 time/temperature treatments under different pressure levels and for different initial water
118 activities on final spore viability were compared.

119

120 2. Material and Methods

121 2.1 Bacterial strain and growth conditions

122 The reference strain *B. subtilis* 168 from the BGSC (Bacillus Genetic Stock Center,
123 Department of Biochemistry, The Ohio State University, USA) was used in this study. *B.*
124 *subtilis* sporulation was induced in a complex medium in a reactor at 37°C, pH 8.0, with an
125 air flow of 4 L/min and with agitation (450 rpm) (Nguyen Thi Minh et al., 2008). Sporulation
126 was estimated by plating on Bromocresol Purple agar (Dextrose Tryptone agar, BIODAR
127 Diagnostics, Beauvais, France) before and after a heat treatment at 80°C for 10 min. When
128 more than 95% of the population in the sample resisted this heat treatment, the spore
129 suspension was harvested (3–5 days). The spore suspension was washed with sterile distilled
130 water four times and was then spray-dried (Mini spray dryer B-290, Buchi, France) and stored
131 in powder form in sterile receptacles at 4°C until use. The final microbial concentration of the
132 powder was approximately 10^{11} CFU/g.

133

134 2.2 Equilibration of spores at different water activities in gaseous and liquid media

135 Dried spores with water activity values of 0.10, 0.20, 0.30, 0.40, 0.50 and 0.70 were obtained
136 by placing the spores (± 500 mg) inside 1 L air-tight plastic boxes containing the
137 water/glycerol solutions presented in Table 1 (the solution occupied 1/10 of the box volume)
138 until equilibrium was reached (at least one week). Water activity determinations of the
139 osmotic solutions and spore powders were performed in triplicate at 25°C using a Decagon-
140 AQUALAB CX-2 water activity meter (Meter, WA, USA).

141 For liquid media, 10 mg of spray-dried spores previously equilibrated at different water
142 activity levels were placed directly in water/glycerol solutions at concentrations predicted by
143 the Norrish Equation to correspond to a_w levels of 0.10 to 0.70 (Norrish, 1966). The
144 experimental a_w values were also checked with the osmometer previously described.

145

146 2.3 Treatment of dried spores in gaseous or liquid medium at high temperature and up to a
147 pressure level of 0.6 MPa

148 The reactor consisted of a small hermetic stainless-steel cylinder (1 cm³ of volume) that could
149 be pressurized with gas. Nitrogen was used to pressurize the reactor, after which the reactor's
150 valve was closed to maintain the applied pressure.

151 2.3.1 Gaseous medium

152 In closed systems containing water, increasing pressure prevents water vaporization.
153 Therefore, if the pressure in the reactor is lower than the pressure of water vaporization (P_{vap})
154 at the considered temperature, water vaporization from the spores will occur until P_{vap} is
155 reached. On the other hand, as soon as the pressure exceeds P_{vap} , no vaporization of the water
156 present in the spores will occur. The final pressure inside the reactor is determined by the
157 input controlled pressure of nitrogen and two modifying factors: i) the pressure increase
158 resulting from increased temperature and ii) the pressure increase resulting from water
159 evaporation from the sample. These factors have been considered to fit the evolution of the

160 water vaporization in the reactor as a function of the total pressure evolution for different
161 initial nitrogen pressures.

162 Figure 1 models the increasing pressure in the vessel for each initial nitrogen pressure level as
163 a function of the increasing temperature and the water vaporization temperature evolution
164 curve. As soon as the temperature/pressure curve crosses the temperature vaporization curve
165 (which occurs for 0.1 MPa, 0.2 MPa and 0.3 MPa at 107, 130 and 145°C, respectively) any
166 liquid water present in the vessel will evaporate from this intersection point until the end of
167 the heat treatment. For the 3 higher initial pressure levels (i.e., 0.4, 0.5 and 0.6 MPa), the 3
168 curves did not cross the water saturation curve before a temperature of 150°C was reached in
169 the experiment (see Figure 1), thus one can assume that there was no evaporation of any
170 liquid water in the vessel from an initial pressure of 0.4 MPa.

171 For most experiments, 10 mg of dried spores were placed in aluminum foil that was folded
172 and placed inside the reactor. The reactor was then pressurized between 0.2 and 0.6 MPa,
173 closed and heated in an oil bath at 150°C. When atmospheric pressure was used, the valve
174 was left open to allow water evaporation. After the treatment, the reactors were cooled in an
175 ice bath, then the valve was opened to release the pressure.

176 2.3.2 Liquid medium

177 For one set of experiments, performed at 0.6 MPa initial pressure and 150°C, the reactor
178 described previously was filled with water-glycerol suspensions at the same five a_w values
179 previously examined in gaseous medium, and 10 mg of spores were added immediately
180 before heat treatment. Under these thermodynamic conditions, there was no vaporization of
181 the different water/glycerol solutions or of pure water.

182 For liquid and gaseous treatment, it was verified that such a pressure level (0.6 MPa) does not
183 alter spore viability. In fact pressure levels greater than 200 MPa are necessary to slightly
184 inactivate spores with gas medium (Colas de la Noue et al., 2012) and 100 MPa in liquid
185 medium (Nguyen Thi Minh et al., 2010a).

186

187 2.4 Spore viability

188 Heat-treated dried spores and spores in liquid medium were serially diluted with physiological
189 saline solution (0.9% NaCl w/v), and 100 µl of each dilution was seeded in triplicate onto
190 BCP agar (Dextrose Tryptone Agar, Biokar Diagnostics, Beauvais, France) plates. Colonies
191 were counted after 24 hours of incubation at 37°C. Control samples contained untreated
192 spores. All experiments were performed at least in triplicate. Spore inactivation was expressed
193 using a logarithmic reduction factor $\log(N_0 - N)/N_0$, with N_0 representing the number of
194 developing spores before treatment and N representing the number of developing spores after
195 treatment.

196

197 2.5 Statistical analysis

198 On each viability point (at least 3 independent measurements) standard deviation was
199 calculated and plotted as error bars on each figure. In order to confirm the effect of pressure
200 level, an ANOVA and Tukey's honestly significant difference test (if $p < 0.05$) were
201 performed to determinate whether significant differences existed among treatment at different
202 pressure. Analyses were performed using the R software, version 3.1.2.

203

204 3. Results

205 3.1 Effect of temperature and pressure on the viability of dried spores in gaseous medium

206 Initial pressures between 0.2 and 0.6 MPa were used to study the effect of pressure combined
207 with heat in *Bacillus* spore inactivation. Spores were equilibrated at a water activity of 0.50,
208 which is a typical a_w for dried foods such as flours, cereals and spices (Lang et al., 2017). The
209 heat treatment (150°C, 120 s) was chosen after preliminary tests that showed these conditions
210 to be discriminative on the ratio of spore viability to mortality.

211 In Figure 2, we show that heat treatment performed with no additional pressure, i.e., 150°C at
212 atmospheric pressure, resulted in a slight destruction level of 0.3 log, which is not
213 significantly different from the control sample maintained at 25°C and which certainly
214 corresponds to the inactivation of pre-germinating or germinating spores.

215 Thus, this treatment did not inactivate any spores, which illustrates their significant
216 thermoresistance. The results presented in Figure 2 also clearly show that when the applied
217 pressure was increased, spore inactivation also increased. Below 0.3 MPa, the inactivation
218 level was found to be less than 3 log, whereas above 0.3 MPa, the inactivation suddenly
219 increased from 4 log CFU for 0.4 MPa to 5 log CFU for 0.6 MPa.

220 An ANOVA performed on these results confirmed that the inactivation levels corresponding
221 to the two pressure level groups (0.2 and 0.3 MPa versus 0.4, 0.5 and 0.6 MPa) were
222 significantly different ($p < 0.05$).

223 To further probe the previous results, the kinetics of spore inactivation was studied at a_w 0.5
224 and 150°C. The pressure used was 0.6 MPa, which corresponded to higher spore destruction
225 in Figure 2. The inactivation of spores with time is shown in Figure 3. Spores heated at
226 atmospheric pressure exhibited only a slight inactivation of approximately 0.5 log after 240 s,
227 whereas spores subjected to 0.6 MPa pressure exhibited an inactivation of 5 log between 60 s
228 and 120 s of treatment.

229 Data from Figures 2 and 3 show that pressure significantly affects the destruction of *B.*
230 *subtilis* spores undergoing a 150°C heat treatment at an a_w of 0.5.
231 This pressure effect exists at all pressure levels but becomes more significant with a gap of 1
232 to 2 log destruction for initial pressure levels greater than 0.4 MPa.

233

234 3.2 Effect of water activity on the viability of dried spores at different times for a 150°C/0.6
235 MPa treatment

236 Dried food products and food powders normally have a water activity ranging from 0.20 to
237 0.50, and in exceptional cases, their a_w may reach 0.70, thus it is important to investigate the
238 effect of this variable on the proposed treatment.

239

240 3.2.1 In gaseous medium

241 The influence of water activity on spore inactivation is presented in Figure 4. These results
242 clearly show that the water activity, and consequently the water content of the spores, plays a
243 fundamental role in spore resistance. Spores equilibrated at an a_w of 0.10 exhibited an
244 inactivation of 5 log after 560 s, whereas spores at an a_w of 0.20 exhibited an inactivation of 8
245 log after the same amount of time. When water activity increased, spore inactivation also
246 increased, as shown by the decrease in logarithmic reduction time (D-values) presented in
247 Table 2. Indeed, the D value is four times greater for an a_w value of 0.10 than for an a_w value
248 of 0.7. Moreover, we found that the same increase in water activity level does not result in a
249 proportional increase in spore inactivation. For example, there is only a small difference
250 between spore inactivation at a_w 0.30 and 0.50, but further increase to an a_w of 0.70 resulted in
251 complete inactivation after only 240 s.

252 It is important to emphasize that, with a pressure of 0.6 MPa, the treatment times are greatly
253 reduced, and so, even for water activity levels as low as 0.10 and 0.20, it is possible to reduce
254 the spore population by a factor of 10 to 5 in approximately 9 or 6 minutes, respectively.

255

256 3.2.2 In liquid medium

257 To build on the previous results, the protective effect of a_w on spore thermal resistance was
258 analyzed in a liquid aqueous medium in the same experimental chamber used for spore
259 inactivation in a gaseous medium. Addition of glycerol in the treatment liquid medium was
260 used to control the a_w of the medium and therefore may have protected spores from heat.
261 However, osmolytes sometimes also have direct toxic effects on spores and interfere with the
262 pure osmotic effect (Mazas et al., 1999). Nevertheless, spores are known for their low
263 permeability to many toxic chemicals, in particular, those that can damage the spore DNA
264 located in the central spore core (Knudsen et al., 2016). Moreover, glycerol, which was used
265 in our experiment, is a compatible solute with very few interactions with other molecules,
266 thus it is an almost ideal solute. Therefore, its action may be mainly related to the a_w decrease.

267 The results shown in Figure 5 demonstrate that the water activity of the treatment medium had
268 a major effect on spore heat inactivation. When heated in higher water activities, spores were
269 more sensitive to heat. Spores treated at a_w 0.10 or 0.20 presented a 2 log reduction after 240
270 s, whereas spores at a_w 0.30, 0.40 and 0.50 presented a 6 log inactivation after only 180 s.

271

272 Spore inactivation began at different treatment times depending on the a_w of the medium and
273 later than we observed for spores treated in dried form (see Figure 3). This result can be
274 explained by the heating kinetics inside the reactor. Indeed, previous experiments (data not
275 shown) have allowed us to verify that the temperature inside the reactor reached 99% of the
276 oil bath temperature in less than 10 s when air/nitrogen was the transmitting medium;

277 however, more than 100 s were needed for pure glycerol and 60 s for pure water to reach the
278 same 99% temperature response. Figure 5 shows that inactivation at an a_w of 0.70 was
279 noticeable between 60 s and 90 s, whereas for lower a_w levels, corresponding to lower spore
280 water content, inactivation started only after 120 s of treatment.

281 Comparing these results with those obtained from dried spores in gaseous conditions (see
282 Figure 3), it can easily be noted that for the same water activity, the final spore inactivation
283 was quite similar.

284

285 4. Discussion

286 Steam treatment is in extensive use today for microbial decontamination of dry foods, but its
287 use presents problems since it results in water condensation on the product that must be
288 removed to avoid subsequent mold growth and spoilage. On the other hand, thermal processes
289 such as microwaves (Kim et al., 2009), infrared (Eliasson et al., 2014) and High Temperature
290 Short Time treatment (Fine and Gervais, 2005a) necessarily involve supplementary drying of
291 the product. Moreover, alternative treatments available for use in aqueous media, such as high
292 pressure and pulsed electric fields, are not efficient for the decontamination of dried foods
293 (Espinasse et al., 2008). Therefore, new procedures for decontaminating dried foods that can
294 destroy bacterial spores are needed.

295 This study investigates the inactivation of dried *Bacillus subtilis* spores equilibrated at
296 different water activities by a treatment using high temperature and absolute pressure levels of
297 nitrogen from 0.2 to 0.6 MPa. In this experiment, the applied pressure prevented water
298 evaporation from the treated samples, allowing the initial water content of the spores, which is
299 mainly situated in the spore core, to be maintained.

300 Inactivation varies from less than 1 log at atmospheric pressure to more than 5 log at 0.6 MPa.
301 Between the initial pressure level of 0.3 MPa at 25°C (which generates 0.43 MPa at 150°C)
302 and the initial pressure 0.4 MPa at 25°C (which generates 0.57 MPa at 150°C), there is a
303 sudden increase in inactivation, in contrast to the slower increase observed at higher
304 pressures. Based on these results, it can be concluded that when the pressure generated in the
305 vessel exceeded the pressure corresponding to the water vaporization temperature of 150°C
306 (0.47 MPa, see Figure 1) the spore inactivation significantly increased, as shown in Figure 2.

307 From this result, it can be proposed that i) maintaining water in the endospore favors bacteria
308 inactivation and that ii) spore drying, which is initiated for pressure levels lower than 0.47
309 MPa, favors bacteria survival at 150°C. Moreover, the drying time and thus the final drying
310 level decreased with increasing pressure until no further drying occurred, when the internal
311 pressure reached the 0.47 MPa value, which corresponded to a nitrogen pressure between 0.3
312 and 0.4 MPa (see Figure 1).

313 One can propose a role of water in spore inactivation in agreement with numerous works
314 (Coleman et al., 2007; Sochava, 1997; Subramanian et al., 2006) in which the internal
315 endospore macromolecules, mainly composed of DNA, DPA, and proteins (the last being the
316 most delicate), are preferentially heat-damaged when mobile and unfolded in a water medium.
317 Moreover, a recent work (Tros et al., 2017) has observed a large fraction of “normal”
318 intracellular water in the spore core of *B. subtilis*.

319 Even for very low water activity levels, noticeable spore inactivation was obtained in liquid as
320 well as in gaseous medium. These results agree with previous work (Tiburski et al., 2014),
321 which has shown a residual high water content in the core even for low a_w -equilibrated
322 spores. This phenomenon was attributed to specific high barrier properties of the internal

323 spore membrane slowing down the thermodynamic balance. Thus, it could be assumed that
324 some water remaining in the core caused macromolecule denaturation.

325 Inactivating one or more key spore proteins is believed to be important in spore heat killing
326 (Coleman et al., 2010). When heat surpasses a threshold level, especially in aqueous media,
327 changes in the structure of vital growth proteins become irreversible, causing spore
328 inactivation (Grinshpun et al., 2010). It is also known that in low moisture states the
329 temperature of protein denaturation increases (Sochava, 1997), making inactivation of these
330 key proteins more difficult. In this context, the high spore heat resistance at low water content
331 can be explained by the low mobility and changes in the conformations of proteins and
332 enzymes. Indeed, most spore proteins are rotationally immobilized, which may contribute to
333 heat resistance by preventing heat-denatured proteins from aggregating irreversibly (Sunde et
334 al., 2009). Consequently, when the original water content of the spore is maintained, protein
335 damage is increased during heat treatment, and such damage is certainly relevant to the
336 differences in spore inactivation found in our experiments. This hypothesis has been directly
337 verified through FTIR measurement in a previous work (Tiburski et al., 2014). Nevertheless,
338 the present results were obtained on *B. subtilis* strain 168 and it is possible that at the pressure
339 and temperature levels used the spore inactivation mechanisms could vary for other bacterial
340 spores.

341

342 Conclusion

343 The model system developed in this work can be extended to treating low water content
344 foods. This system is based on the application of temperature under pressure, which prevents
345 any water evaporation from bacterial spores embedded in the food product. This model has
346 the advantage of not adding moisture to the product, and it results in high spore destruction
347 rates (approximately 5 log). The efficiency of this process is related to the high water

348 permeability barrier of the internal membrane of the spore, which has been shown to allow
349 maintenance of a core water content greater than the outer membrane long after drying. Thus,
350 this new process is particularly efficient for dried bacteria spore destruction because of their
351 high residual core water content. Further studies must first verify this effect on other
352 sporulated strains and especially pathogens. In a second phase, we must integrate the impact
353 of such pressure/temperature/time treatments on the organoleptic and nutritional properties of
354 different dried food products. Indeed, optimal treatments should conserve the functional
355 properties of food in addition to assuring maximal bacteria spore inactivation. Following this
356 work, this process could then be tested to treat dried food products such as spices. The normal
357 a_w of dried food ranges between 0.30 and 0.50, and in this work, we have shown that spore
358 inactivation higher than 5 log can be expected from a 3 minute treatment at these water
359 activities. Therefore, if the products already possess a similar a_w , no previous equilibration
360 will be needed; however, if the product to be processed has a very low a_w , an equilibration
361 step would be necessary. In this case, the dried food could be stored in an atmosphere with a
362 relative humidity of 50% for a few weeks prior to treatment. Certainly, different conditions of
363 time, temperature and pressure adapted to each product will need to be tested to optimize this
364 new decontamination procedure.

365 The next step would be to develop a scaled-up version of the system to perform tests in real
366 food products to evaluate both microbiological decontamination and changes in quality
367 parameters.

368 Acknowledgments

369 This work is supported by the Conseil Régional de Bourgogne through the plan d'actions
370 régional pour l'innovation (PARI) and the European Union through the PO FEDER-FSE

371 Bourgogne 2014/2020 programs. The PhD of Julia Hauck Tiburski was funded by the
372 Coordenação de Aperfeiçoamento de Pessoal de Nível Superior (CAPES-Brazil).
